

Chapter 1

Mechanisms of denitration

1.1 Introduction

The first stage of thermolytic decomposition for nitrate esters is widely considered to be homolytic fission of the O-N bond linking the nitrate to the alkyl chain, leading to the loss of $\cdot\text{NO}_2$ (equation 1.1) [?]. Though nitrate homolysis is an endothermic reaction, the weak O-N bond has a typical dissociation enthalpy of 42 kcal mol⁻¹ and is easily cleaved when exposed to elevated temperatures, UV light or impact. Whilst the thermolytic degradation of energetic materials has been widely studied experimentally, the ambient, slow ageing mechanisms are less well documented. Low-temperature decomposition routes are influenced by many factors over a protracted lifetime, and in practical use, materials are usually subject to evolving environmental conditions. External changes in pressure, humidity, stress and temperature cycles induce variation in the degradation patterns of energetic materials. The presence of moisture has been observed to lower the activation energy and accelerate the decomposition of energetic materials [?]. Internal factors including impurities and residual solvent, and crystal growth within the bulk, also alter decomposition behaviour.

The decomposition of nitrate esters at temperatures over 100°C is dominated by thermolytic processes, whilst under 100°C, decomposition is thought to largely be the result of hydrolysis [?]. Tsyshevsky *et al.* studied the intramolecular reactions leading to denitration in **PETN!** (**PETN!**) in both the vacuum and the bulk crystal [?] (figure 1.1). It was found that the two dominating decomposition reactions were homolysis (equation 1.1) and intramolecular elimination of HNO₂ (equation 1.2).

1. ·NO₂ loss
2. HNO₂ loss
3. OONO rearrangement
4. γ-attack
5. ONO₂· loss
6. C–C cleavage (CH₂O + NO₂)
7. C–C cleavage (CO + HNO₂)

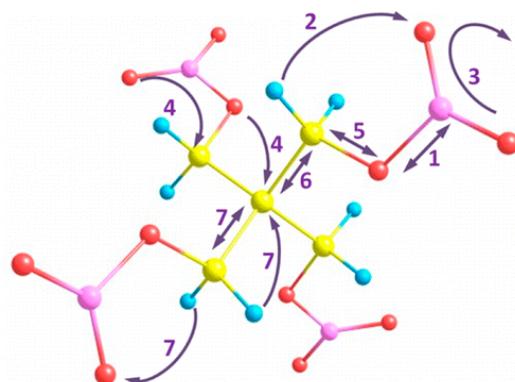

Figure 1.1: Intramolecular thermolytic reactions in PETN!, from the work of Tyshevsky *et al.* [?].

Whilst elimination of HNO₂ was found to be the most energetically favourable denitration pathway, homolytic fission dominated preliminary decomposition steps due to the lower activation barrier and faster rate of reaction. It was suggested that global decomposition processes were determined by the interplay between the two mechanisms. Initial homolysis facilitated wide-spread denitration, complemented by exothermic HNO₂ elimination promoting self-heating of the system and further bond dissociations. The presence of ·NO₂ and HNO₂ were previously linked to observed autocatalytic rates of later-stage decomposition [?, ?, ?]. However, from these initial processes it is not possible to determine which is the autocatalytic species (this topic is further discussed in the next chapter.)

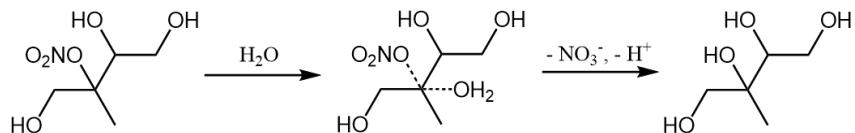

Spent acids remain in the NC! (NC!) matrix following synthesis even with thorough washing procedures. Acids are further generated via the subsequent reactions of ·NO₂ following homolysis. The acidic species proceed to react with other moieties in the system, such as unsubstituted alcohol side chains on the polysaccharide, or other small molecules free in the bulk. When exploring the interaction of nitroglycerol and nitroglycerin in acid solution, Camera proposed a protonation-denitration scheme whereby initial protonation at the nitrate is rapid, but subsequent release of the nitronium ion was slow (scheme 1.1).

NC! in storage is kept wetted with solvents to prevent drying and self-ignition. Material with 12.6pN! or lower, must be stored in 25% water by mass, or a mixture of solvents and plasticisers. In the study of organonitrates and organosulfates generated from isoprene as secondary organic aerosols, Hu *et al.* found that primary and secondary nitrates were

Scheme 1.1: The relative rate of stepwise protonation and denitration of nitrate esters, using ethyl nitrate as an example. From the work of Camera *et al.* [?].

resilient to hydrolysis for pH > 0, whilst tertiary nitrates underwent hydrolytic nucleophilic substitution easily, reacting with water to form alcohols [?]. Primary nitrates are those with

Scheme 1.2: Hydrolysis of a tertiary nitrate derived from the reaction of isoprene in the aerosol phase, from the work of Hu *et al.* [?].

one non-hydrogen moiety on the carbon, (additional to the nitrate linkage) with the remaining two bonds linked to hydrogens. Secondary nitrates are those where the nitrate carbon possesses one bonded hydrogen atom, and two further non-hydrogen moieties. In tertiary nitrates, the carbon is fully substituted with no attached hydrogens. This latter group is usually sterically hindered and stabilising to carbocations, condition on the other substituents. If formation of a carbocation intermediate is involved in the hydrolysis mechanism, this may explain why the tertiary nitrates exhibited highly efficient denitration, even under neutral conditions.

Though no specific mechanistic detail is given, the action of a protonated transition state during hydrolysis is alluded to by Hu *et al.*, through the contrast between the rate of acid-catalysed and neutral hydrolysis reactions. Neutral hydrolysis of the tertiary nitrates occurred rapidly, but hydrolysis only occurred for primary and secondary nitrates under strongly acid catalysing conditions at much lower rate. It was found that the presence of adjacent OH groups hampered the rate of hydrolysis for some aerosol dispersed organonitrates. In the neutral hydrolysis of tertiary nitrates, increasing the number of adjacent OH groups lead to protracted hydrolysis lifetimes. Interestingly, the retardation effect of adjacent OH groups was not observed for the acid catalysed cases. Hu proposed that this could be due to the interaction of OH with the transition state of the neutral hydrolysis system, compared to the protonated transition state of the acid catalysed system, impeding

the reaction only in the former case. There is evidence that nitration and denitration of nitrate esters is also influenced by the presence of nitrate groups at neighbouring positions. Matveev *et al.* demonstrated that for poly-nitroesters the rate of liquid-phase decomposition did not increase linearly with number of nitrate reaction centres. It was found to mainly dependend on individual structures (table 1.3) [?].

It was suggested that the trend in reactivity could be partially explained by the inductive effect of the nitro groups [?]. The inductive effect arises when a difference in the electronegativity between atoms connected by a σ bond leads to a polarisation, or permanent dipole, in the bond. Electron donating groups increase the $\delta-$ partial charge on neighbouring atoms through the release of electrons, whilst electron withdrawing groups pull electron density away from neighbouring atoms generating a $\delta+$ charge on connected atoms. However, the π donation by lone pairs on the oxygen and nitrogen plays a significant role in increasing electron density of neighbouring atoms, known as the resonance effect. NO_3 presents a stronger electron donating effect via π donation than OH , though both groups are activating. It would therefore be expected that both increase the rate of hydrolysis for nearby leaving groups. The presence of an adjacent nitrate appears to facilitate denitration, whereas the presence of hydroxyl groups hinders this process, for neutral hydrolytic schemes. This suggests that the proposed interaction of the hydroxyl group with the neutral transition state supersedes its resonance effect. As a result, it is ambiguous whether any apparent rate in-

Table 1.1: Comparison of rate constants of decomposition for various polynitrate esters at 140°C. Collated from literature sources by Matveev *et al.*[?]. ΔT is the decomposition temperature range, E is the experimental activation barrier for decomposition, $\log A$ is the pre-exponential factor, T_c is the combustion temperature, k_{expt} is the rate constant for decomposition.

| Compound | ΔT / °C | E / kcal mol ⁻¹ | $\log A$ [s ⁻¹] | k_{expt} / 10 ⁻⁶ s ⁻¹ |
|-----------------------------------------------------------------------------------------------------|--------------------|---------------------------------|--------------------------------|---------------------------------------------------------|
| $\text{O}_2\text{NOCH}_2\text{CH}_2\text{CH}_2\text{ONO}_2$ | 72–140 | 39.1 | 14.9 | 1.7 |
| $\text{O}_2\text{NOCH}_2\text{CH}_2\text{CH}_2\text{CH}_2\text{ONO}_2$ | 100–140 | 39.0 | 14.7 | 1.1 |
| $\text{O}_2\text{NOCH}(\text{CH}_3)\text{CH}(\text{CH}_3)\text{ONO}_2$ | 72–140 | 40.3 | 14.9 | 5.0 |
| $\text{O}_2\text{NOCH}_2\text{CH}_2\text{OCH}_2\text{CH}_2\text{ONO}_2$ | 80–140 | 42.0 | 16.5 | 1.9 |
| $\text{O}_2\text{NOCH}_2\text{CH}(\text{OH})(\text{CH}_2\text{ONO}_2)$ | 80–140 | 42.4 | 16.8 | 2.3 |
| $\text{O}_2\text{NOCH}_2\text{CH}(\text{ONO}_2)(\text{CH}_3)$ | 72–140 | 40.3 | 15.8 | 3.0 |
| $[(\text{O}_2\text{NOCH}_2)\text{CH}(\text{ONO}_2)\text{CH}(\text{ONO}_2)]_2$ (hexanitromannite) | 80–140 | 38.0 | 15.9 | 63.0 |

crease due to the presence of adjacent nitrate groups arises as a result of the resonance effect of the nitrate, or whether it is solely due to the absence of a neighbouring hydroxyl.

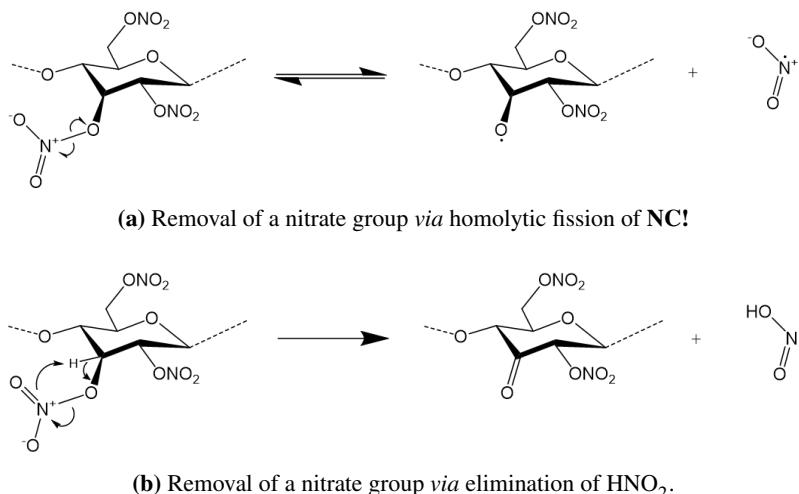

The investigation by Hu *et al.* exclusively focused on nitrates generated from an isoprene precursor, upon dispersion as an aerosol. The nitrate groups present in **NC!** are either of primary (C6) or secondary (C2, C3) structure, indicating that ambient hydrolysis is unlikely according to this scheme. However, solvent effects are expected to differ for condensed-phase reactions and aerosol phases. A greater build-up of acid concentration can be achieved in a closed, condensed system, and the lifetime of an aerosol is relatively short-lived when considering the timescale of slow ageing processes in **NC!**. Thus, the work of Hu *et al.* does not provide a direct comparison for the **NC!** polymer but highlights the the possible contribution from both neutral and acid-catalysed hydrolysis routes and of increasing levels of substitution on the wider structure. In this section, the possible mechanisms for nitrate removal from the **NC!** backbone are explored. The homolytic fission and HNO_2 elimination thermolytic processes suggested by Tsyshhevsky will be compared to the acid hydrolysis scheme. The energies of reactions will be compared, with derivation of the reaction rate where it is possible to isolate a transition state.

1.2 Methodology

The energies of homolytic fission and elimination of HNO_2 were calculated for PETN, as a test system before extension to the monomer. The reaction energies were calculated according to equations 1.1 and 1.2 to reproduce the work of Tsyshhevsky *et al.* . The literature geometries of PETN and the reaction products were obtained from the authors. A single point energy and frequency calculation were performed on each of the relevant structures to determine the reaction energies; no geometry optimisation was performed.

The intramolecular reactions of the **NC!** monomer were modelled according to scheme 1.3. Rigid and relaxed PES! (PES!) scans were attempted in order to locate transition states for both reactions for the **NC!** monomer. Where the scans were unable to identify a valid transition state geometry, guess transition state geometries were constructed and optimised.

The possible protonation sites for the **NC!** monomer were explored by placing a proton at each of the different oxygen sites surrounding the nitrate group. The structures were then geometry optimised and energies of protonation were compared. H_3O^+ was modelled as the donating species; as **NC!** is usually stored wetted in water, the hydronium ion is the most likely source of protons. It is also possible that the proton is donated by other acidic species

Scheme 1.3: The proposed intramolecular reactions for the initial denitration step during NC! degradation.

in the system, particularly HNO₂ or HNO₃. This is more likely at later stages of degradation when a higher concentration of acid has been generated by secondary reactions. The effects of tunneling were not accounted for.

1.2.1 Computational details

All geometry optimisation, thermochemistry calculations and PES! scans were performed in G09! (G09!). Geometry optimisation and thermal calculations were to the level of 6-311+G(d,p). NC! monomer structures were optimised using wb97xd! (wb97xd!), B3LYP! (B3LYP!) and MP2! (MP2!). ΔG values were obtained by the difference between the thermally corrected free energies of products and reactants. Zero-point corrected energies ZPE! were determined by addition of individual ZPE! (ZPE!) to the free energy:

$$\Delta G^{corr} = (G_{products} + ZPE_{products}) - (G_{reactants} + ZPE_{reactants}) \quad (1.5)$$

PES! scans were performed to the level of wb97xd!/6-31+g(d), or unrestricted wb97xd!, in the case of O-NO₂ dissociation. Rigid scans were carried out by fixing bond lengths, angles and dihedral values as constants. Only the variable of interest was allowed to change, with specified relaxation of any other coordinates required for accommodation of the new geometry, following each step of the variable. For example, in the simultaneous ('dual') scan of the approach of a hydrogen, with current elongation of the O-NO₂ bond of the nitrate, the angle of the departing NO₂ with respect to the remainder of the molecule was allowed to relax. Relaxed scans were performed in Gaussian using the 'modredundant'

function, whereby the whole structure was permitted to relax after each step of the variable. Scans were performed with step size of 0.1 Å, Scans were attempted in vacuum, and for some cases, **PCM!** (**PCM!**) implicit solvent [?].

The protonation studies conducted in solvent were calculated in **PCM!** ...

1.3 Results and discussion

1.3.1 Thermolytic decomposition mechanisms

The energies of homolytic fission and intramolecular elimination of HNO₂ from a **PETN!** nitrate group are shown in table 1.2. The energy values calculated by Tsyshevsky *et al.* are denoted in parenthesis. Despite using the supplied geometries, same method and basis, it can be seen that the reaction energies obtained for PETN vary greatly from the values found by Tsyshevsky *et al.*. Inspection of the forces showed that they were in fact not converged. It was assumed that the given geometries matched those used to generate the reaction energy values quoted in the study. The unconverged structures therefore do not fully explain the large discrepancy between the literature energies and values that were derived here, though a possible explanation may be that different geometries were used for the values obtained in the study. A small contribution may arise from a different compilation of the **G09!** program, leading to small fluctuations in the exact values obtained which are amplified when deriving reaction energies.

Table 1.2: Calculated free energies of reaction (ΔG_r), reaction enthalpies (ΔH_r), activation barriers (E_a) with zero-point correction (ZPE) for the intramolecular reactions of PETN, and the **NC!** monomer. Values expressed in kCal mol⁻¹.

^b values for the energy barrier and total energy of reaction are the same, treating homolytic fission as a barrierless process.

A PES! scan was performed on the NC! where the O–NO₂ bond was elongated, to simulate homolytic fission. Unrestricted wb97xd! was used, with 20 steps of 0.1 Å...

1.3.2 Acid hydrolysis mechanism

1.3.2.1 Protonation site

The protonated NC! monomer species are shown in figure 1.2. Protonation also occurs on other sites in the molecule, such as at unsubstituted hydroxyl groups, the capping group oxygen on C4 and O1 in the glucose ring. However, for the purposes of studying denitration via acid hydrolysis, only the sites peripheral to the nitrate leaving group were explored. There is a possibility that protonation at further sites in the monomer would contribute to degradation processes *via* alternative mechanisms. Whilst the mechanism of protonation

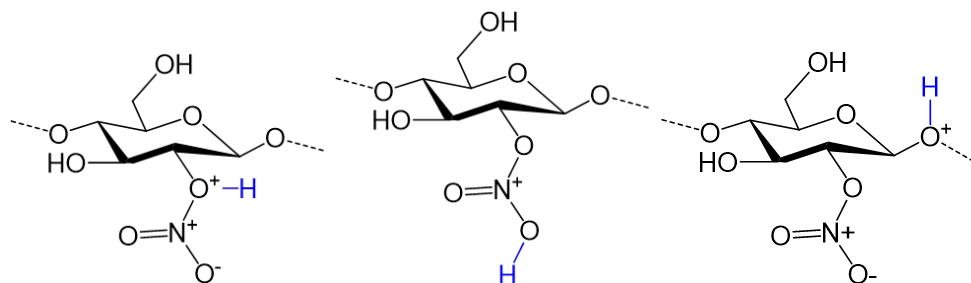

Figure 1.2: Protonation sites on the NC! monomer for hydrolysis of the nitrate at the C2 position.

was not explored in depth here, it was assumed that the protons in the system would be in fast exchange between the molecule and the solvent. The process has been thoroughly explored computationally by X *et al.*. Evaluation of the energy of protonation at each site

Table 1.3: Free energies of protonation at each of the oxygen sites of interest on CH3CH3! (CH3CH3!) C2 monomer of NC!.
